# 1. Agenda and recap

## 1.1 Today

- What a regression line (OLS) does, in pictures
- How the line becomes a prediction formula
- How to read a simple journal-article regression table
- How to turn coefficients into a prediction for a change in (X)
- Brief: what if the model is not OLS? (logit, probit, etc.)

## 1.2 Where we are in the course

- We have talked about variables, distributions, and relationships.
- We have seen scatterplots and talked about “positive” and “negative” relationships.
- Today we move from describing a relationship to writing *a specific line* that summarizes it.

# 2. What OLS is doing (no heavy math)

## 2.1 A cloud of points and a line

- Imagine a scatterplot of (X) (e.g., income) and (Y) (e.g., turnout).
- Many lines could be drawn, but some will “fit” the points better than others.
- Ordinary Least Squares picks **one** line as “best.”

## 2.2 “Best” in the OLS sense

- For each point, the *residual* is “actual (Y) minus predicted (Y).”
- OLS chooses the line that makes the *squared residuals* as small as possible overall.
- Visually: the chosen line keeps the vertical distances from the points to the line as small as possible *on average*.

## 2.3 Video example

Show the video example here

## 2.4 Visual example (graphic)

*Regression line drawn through a cloud of points, showing vertical distances (residuals) from each point to the line*

## 3. Turning the line into a formula

### 3.1 The basic regression equation

- The line can be written as a formula:  
 $[ = a + bX ]$
- (a) is the **intercept** (predicted (Y) when (X = 0)).
- (b) is the **slope** (how much we expect (Y) to change when (X) increases by 1 unit).

### 3.2 Interpreting the slope

- If (b = 2), then when (X) increases by 1 unit, predicted (Y) increases by 2 units.
- If (b = -0.5), a 1-unit increase in (X) is associated with a 0.5-unit *decrease* in predicted (Y).

- The slope is the “effect” of (X) on (Y) in this simple model.

### 3.3 Example with a story

- Suppose (Y =) political knowledge score (0–10) and (X =) years of education.
- If the estimated line is ( $= 2 + 0.3X$ ), then:
  - A person with 10 years of education has predicted knowledge ( $= 2 + 0.3(10) = 5$ ).
  - A person with 14 years of education has predicted knowledge ( $= 2 + 0.3(14) = 6.2$ ).
- Going from 10 to 14 years (a 4-year increase) raises predicted knowledge by ( $0.3 \times 4 = 1.2$ ) points.

## 4. Reading a simple regression table

### 4.1 What a one-variable regression table looks like

In a journal article, a very simple OLS table for one (X) might look like this:

| Variable          | Coefficient | Std. Error |
|-------------------|-------------|------------|
| Education (years) | 0.30        | 0.05       |
| Constant          | 2.00        | 0.40       |

- “Coefficient” is the estimate of (b) (for Education) or (a) (for the Constant).
- “Std. Error” is a measure of uncertainty, but today we focus on using the **coefficients** for predictions.

### 4.2 Turning the table into the formula

- From the table, the **intercept** is 2.00.
- The **slope** for Education is 0.30.
- So the regression line is:  $[ = 2.00 + 0.30 ]$

### 4.3 Using the formula for prediction

- If a person has 12 years of education:
  - ( $= 2.00 + 0.30(12) = 5.6$ ).
- If a person has 16 years of education:
  - ( $= 2.00 + 0.30(16) = 6.8$ ).
- The model gives a *predicted* knowledge score for any value of education.

## 5. From change in X to change in Y

### 5.1 The key idea

- In a simple line ( $= a + bX$ ), the slope ( $b$ ) tells us the change in predicted ( $Y$ ) for a 1-unit change in ( $X$ ).
- For a bigger change in ( $X$ ), multiply ( $b$ ) by the size of that change.
- This is often what authors mean by “substantive effect.”

### 5.2 Step-by-step method students should use

1. Read the coefficient for the variable ( $X$ ) of interest (this is ( $b$ )).
2. Decide on a realistic change in ( $X$ ) (for example, 4 extra years of education).
3. Multiply the coefficient by that change in ( $X$ ).
4. Interpret the result as the predicted change in ( $Y$ ).

### 5.3 Worked example

Using the table above:

- Coefficient on Education: ( $b = 0.30$ ).
- Consider a change in Education from 10 to 14 years ( $(X = 4)$ ).
- Predicted change in ( $Y$ ) is:  $[ = b X = 0.30 = 1.2 ]$
- Interpretation: increasing education from 10 to 14 years is associated with a 1.2-point increase in predicted knowledge.

### 5.4 Another example with a different outcome

- Suppose an article has ( $Y =$ ) turnout percentage in a district and ( $X =$ ) campaign spending (in thousands of dollars).
- If the coefficient is ( $b = 0.8$ ), then:
  - A \$10,000 increase in spending ( $(X = 10)$ ) leads to a predicted turnout change of  $(0.8 = 8)$  percentage points.
- Students can always ask: “For a realistic change in ( $X$ ), how big is the predicted change in ( $Y$ )?”

## 6. Very brief: other models in articles

### 6.1 Why you might see models that are not OLS

- Some outcomes are not continuous numbers (e.g., yes/no, counts, ordered categories).
- Authors use other models that fit the outcome type better.
- Common ones in political science:

- Logistic regression (logit)
- Probit
- Count models (Poisson, negative binomial)
- Ordered logit/probit

## 6.2 What stays the same conceptually

- There is still an equation linking (X) to a prediction for (Y).
- The model still has **coefficients** that describe how changes in (X) affect the prediction.
- We can still think in terms of:
  - Coefficient (b) effect of one-unit change in (X).
  - Bigger change in (X) (ΔX) coefficient times that change.

## 6.3 What changes compared to OLS

- In OLS, the line is directly in the units of (Y).
- In logit/probit, the equation predicts something like a *transformed* version of the probability (not raw (Y) itself).
- Authors often help by converting results into:
  - Predicted probabilities for particular values of (X).
  - “Marginal effects” that say “a one-unit change in (X) changes the probability of (Y=1) by so many percentage points.”

## 6.4 How students can read these models at this level

- Focus on the **direction**: is the coefficient positive or negative?
- Focus on whether authors say the effect is “large,” “small,” or “not statistically significant.”
- When authors provide predicted probabilities or marginal effects, read those the same way you did for OLS:
  - For a change in (X), how much does the predicted probability change?

# 7. Wrap-up and practice

## 7.1 Key takeaways

- OLS chooses a single regression line to summarize the relationship between (X) and (Y).
- The line becomes a simple formula:  $\hat{Y} = a + bX$ .
- Given the coefficient (b), a change in (X) of size (ΔX) leads to a predicted change in (Y) of (b ΔX).

- Other models in articles still link (X) to a prediction; you can read direction and size of effects even without the math.

## 7.2 Practice Table

| Variable           | Coefficient | Std. Error |
|--------------------|-------------|------------|
| Political interest | 1.50        | 0.30       |
| Constant           | 20.00       | 2.00       |

Y political knowledge index on a 0–10 scale, X political interest on a 1–5 scale.

## 7.3 Practice questions

1. Write the regression line formula based on the table.
2. Write the effect in a sentence: “A one-unit increase in political interest is associated with a \_\_\_-point increase in the predicted political knowledge index.”
3. What is the predicted  $Y$ , political knowledge index, for someone with a political interest score of 3?
4. If political interest increases from 2 to 4, what is the predicted change in the political knowledge index?
